 Supplemental content

IMPORTANCE Powassan virus is a rare but increasingly recognized cause of severe neurological disease.

OBJECTIVE To highlight the diagnostic challenges and neuropathological findings in a fatal case of Powassan encephalitis caused by deer tick virus (lineage II) in a patient with follicular lymphoma receiving rituximab, with nonspecific anti-GAD65 antibodies, who was initially seen with fever and orchiepididymitis.

DESIGN, SETTING, AND PARTICIPANTS Comparison of clinical, radiological, histological, and laboratory findings, including immunohistochemistry, real-time polymerase chain reaction, antibody detection, and unbiased sequencing assays, in a single case report (first seen in December 2016) at an academic medical center.

EXPOSURE Infection with Powassan virus.

MAIN OUTCOMES AND MEASURES Results of individual assays compared retrospectively.

RESULTS In a 63-year-old man with fatal Powassan encephalitis, serum and cerebrospinal fluid IgM antibodies were not detected via standard methods, likely because of rituximab exposure. Neuropathological findings were extensive, including diffuse leptomeningeal and parenchymal lymphohistiocytic infiltration, microglial proliferation, marked neuronal loss, and white matter microinfarctions most severely involving the cerebellum, thalamus, and basal ganglia. Diagnosis was made after death by 3 independent methods, including demonstration of Powassan virus antigen in brain biopsy and autopsy tissue, detection of viral RNA in serum and cerebrospinal fluid by targeted real-time polymerase chain reaction, and detection of viral RNA in cerebrospinal fluid by unbiased sequencing. Extensive testing for other etiologies yielded negative results, including mumps virus owing to prodromal orchiepididymitis. Low-titer anti-GAD65 antibodies identified in serum, suggestive of limbic encephalitis, were not detected in cerebrospinal fluid.

CONCLUSIONS AND RELEVANCE Owing to the rarity of Powassan encephalitis, a high degree of suspicion is required to make the diagnosis, particularly in an immunocompromised patient, in whom antibody-based assays may be falsely negative. Unbiased sequencing assays have the potential to detect uncommon infectious agents and may prove useful in similar scenarios.

Powassan virus (POWV), first isolated in Powassan, Ontario, Canada, in 1958, is a rare but increasingly recognized tick-borne flavivirus that can cause life-threatening neuroinvasive disease.^{1,2} An average of 7 cases per year are reported in the United States, predominantly in the spring and summer months, from the Northeast and the Great Lakes regions. The following 2 serologically indistinguishable lineages have been described: (1) POWV (lineage I, transmitted by *Ixodes cookei*) and (2) deer tick virus (DTV) (lineage II, transmitted by *Ixodes scapularis*). Approximately 10% of neuroinvasive cases are fatal, and half of the nonfatal cases develop severe neurological sequelae. No vaccines or specific treatments are currently available. Magnetic resonance imaging (MRI) of the brain often demonstrates basal ganglia T2-weighted hyperintensity, but abnormalities can also be seen within the cerebral cortex, thalami, brainstem, and cerebellum.³ Cerebrospinal fluid (CSF) typically reveals a lymphocytic pleocytosis but may be polymorphonuclear predominant early in the disease, with normal or slightly elevated protein level and normal glucose level.¹ Laboratory confirmation of POWV is typically made by detection of IgM antibodies in serum or CSF. Neuropathological findings are similar to other arbovirus infections, including marked edema, necrosis, microglial nodules, neuronophagia, and perivascular, parenchymal, and leptomeningeal inflammation.^{2,4} We present the clinical, radiological, and pathological findings in a diagnostically challenging and ultimately fatal case of Powassan encephalitis because of DTV (lineage II).

Methods

Serum and CSF real-time polymerase chain reaction (RT-PCR) (targeting POWV genome nucleotide genome position 10 617 to 10 668) and IgM-capture enzyme-linked immunoabsorbent assay (with inactivated virus) testing was performed by the Centers for Disease Control and Prevention Division of Vector-Borne Diseases (Fort Collins, Colorado). Immunohistochemistry (using mouse ascitic fluid generated against POWV) and RT-PCR of brain tissue with sequencing of the flavivirus nonstructural protein 5 gene (*NS5*) were performed by the Centers for Disease Control and Prevention Infectious Diseases Pathology Branch (Atlanta, Georgia).⁵ Unbiased metagenomic next-generation sequencing (mNGS) of total RNA extracted from CSF was performed, and the genomic data were analyzed using a previously described bioinformatics pipeline under research protocol 13-12236 at the University of California, San Francisco.⁶

Results

A man in his early 60s from Cape Cod, Massachusetts, with follicular lymphoma receiving maintenance rituximab therapy (the last dose had been administered 2 months prior) was first seen at a community hospital emergency department in December 2016, with 1 week of testicular pain and fever. Testicular ultrasonography demonstrated orchiepididymitis, and

Key Points

Question What is the most efficient way to diagnose Powassan encephalitis in an immunocompromised patient?

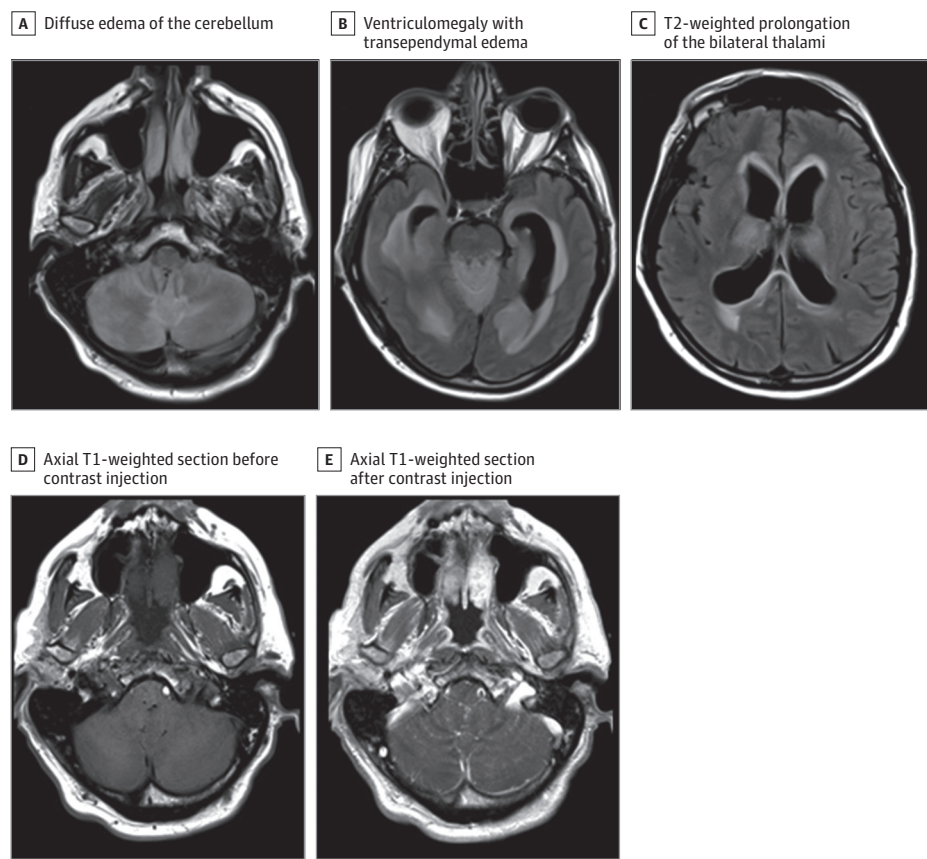

Findings In this case report of a patient with fatal Powassan encephalitis with negative serology, diagnosis was made by Powassan virus immunohistochemistry, targeted real-time polymerase chain reaction, and metagenomic next-generation sequencing.

Meaning In immunosuppressed patients, many tools can be used to make a diagnosis when routine testing results are negative, including unbiased sequencing assays.

he was discharged on a regimen of levofloxacin. Three days later, he developed dysarthria and gait instability and was admitted. Physical examination revealed low-grade fever, dysarthria, meningismus, and bilateral upper extremity dysmetria. At admission, peripheral blood contained 0% CD20+ lymphocytes, and lumbar puncture demonstrated 10 nucleated cells per microliter (60% lymphocytes and 40% neutrophils), glucose level of 62 mg/dL, and total protein level of 83 g/dL (to convert glucose level to millimoles per liter, multiply by 0.0555; to convert protein level to grams per liter, multiply by 10.0). The patient was treated with vancomycin hydrochloride, ceftriaxone sodium, ampicillin sodium, and acyclovir sodium for presumed meningoencephalitis. Head computed tomography without contrast showed no hemorrhage, large territorial infarction, or mass effect. Six days after initial presentation, the patient became obtunded, prompting intubation and transfer to Brigham and Women's Hospital. Examination off sedation was notable for Glasgow Coma Scale score of 4T for lack of eye opening, absent response to pain, and intubation status. Brainstem reflexes were present, deep tendon reflexes were symmetric, and toes were plantar bilaterally. Magnetic resonance imaging of the brain showed diffuse cerebellar edema, obstructive hydrocephalus, diffuse leptomeningeal enhancement, and periventricular, thalamomesencephalic, and basal ganglia T2-weighted signal abnormality (Figure 1). He received hyperosmolar therapy and underwent emergent extraventricular drain placement, followed by decompressive suboccipital craniotomy and cerebellar biopsy. Despite aggressive intervention, the patient's neurological examination findings remained poor, and he was treated empirically with intravenous immunoglobulin and corticosteroids, without improvement.

The patient's broad-spectrum antibiotics were eventually narrowed to ceftriaxone and doxycycline hyclate after his family reported a recent tick bite. Extensive infectious workup was negative for bacterial, fungal, and parasitic infections, including Lyme, syphilis, *Cryptococcus*, and *Toxoplasma*. Viral serum and CSF studies were negative for Herpesviridae, HIV-1, JC virus, mumps, lymphocytic choriomeningitis virus, eastern equine encephalitis virus, western equine encephalitis virus, La Crosse encephalitis virus, Saint Louis encephalitis virus, and West Nile virus (WNV). Cerebrospinal fluid flow cytometry and cytology showed no evidence of malignant cells. A serum paraneoplastic panel demonstrated borderline GAD65 antibody posi-

tivity (0.12 nmol/L; reference range, ≤ 0.02 nmol/L); however, CSF GAD65 was negative. Powassan virus RNA was detected by RT-PCR in serum and CSF (on hospital day 14), while IgM-capture enzyme-linked immunoabsorbent assay was negative in both samples; these results were reported several weeks after death. Cerebrospinal fluid mNGS generated 23 812 828 paired-end sequences. After multiple rounds of filtering out low-quality, redundant, and human sequences, 182 992 unique, non-human read pairs (0.8%) remained. Four of these sequence pairs aligned with 98.4% similarity to the polyprotein of DTV lineage II (GenBank [HM440559](#)) and only 88.9% similarity to the POWV lineage I (GenBank [HM440563.1](#)). The remaining sequences aligned to common laboratory contaminants. Sanger sequencing of the amplicon generated from subsequent RT-PCR on the CSF sample (targeting POWV nucleotide genome position 9091 to 10 123) was also consistent with DTV lineage II (Figure 2C) (GenBank [MG196295](#)). Cerebellar biopsy results revealed a prominent T-cell infiltrate involving the leptomeninges and cerebellar cortex with Purkinje cell loss and Bergmann gliosis (Figure 2A and B).

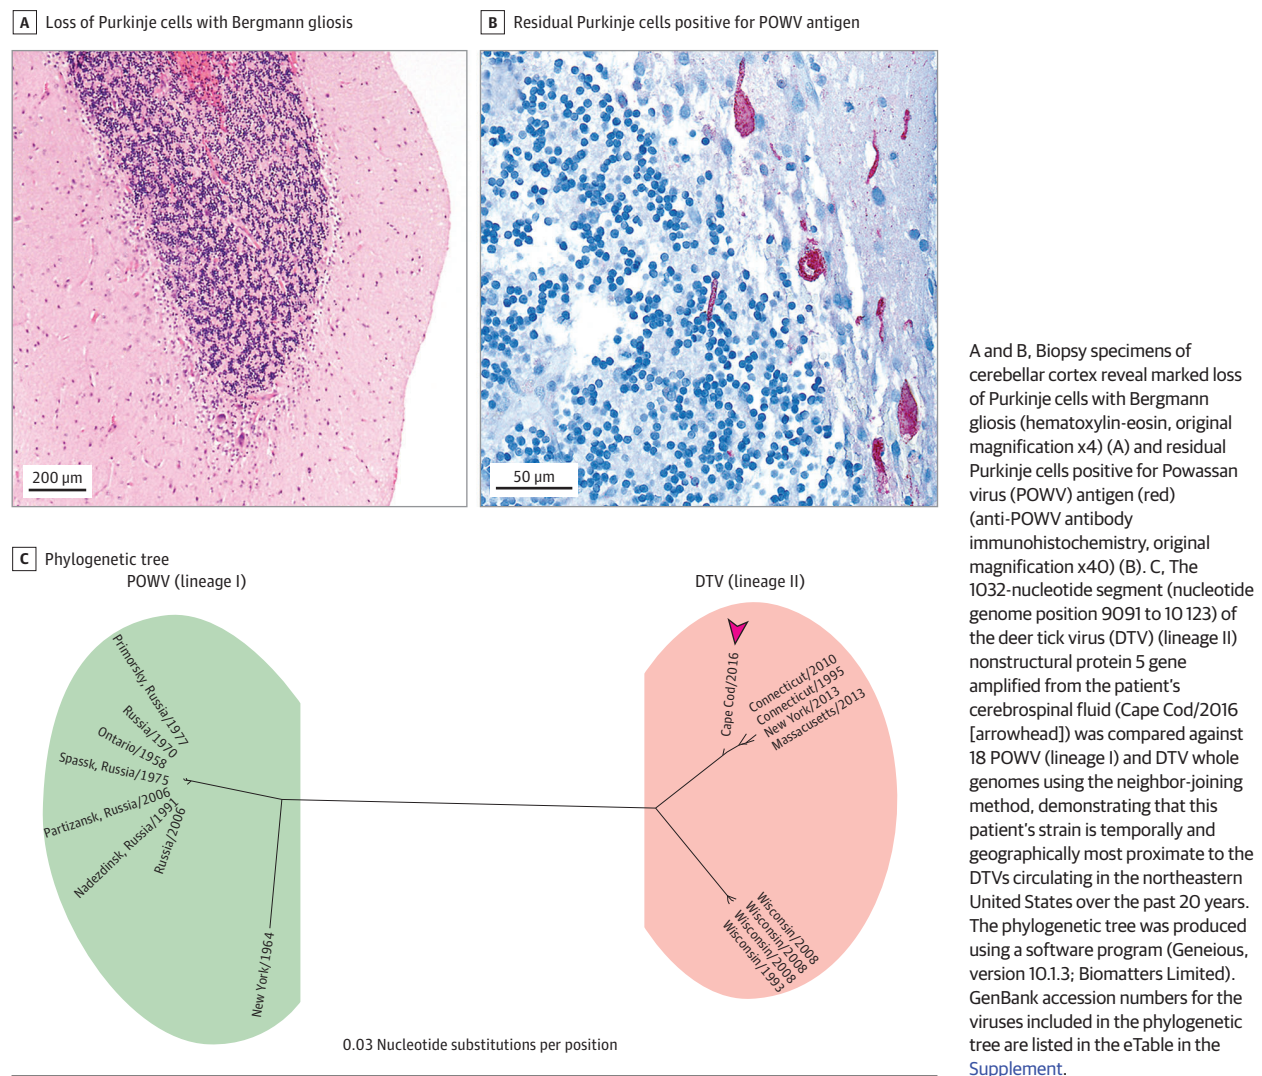

Owing to continued clinical deterioration, the patient was transitioned to comfort care and died on hospital day 14 (19 days after initial presentation). Full autopsy was performed and did not reveal evidence of active follicular lymphoma. The left testicle contained nonspecific chronic inflammation and positive staining for POWV antigen (eFigure, G and H in the [Supple-](#)

[ment](#)). Examination of the brain (1610 g; normal range, 1250-1400 g) revealed significant edema. Microscopic findings were most prominent in the cerebellum and consisted of diffuse severe Purkinje cell loss, gliosis, microglial nodules, multifocal infiltration of macrophages and T cells, numerous cerebellar white matter microinfarctions with diffuse axonal loss, and severe loss of neurons in the dentate nucleus (eFigure, A-F in the [Supplement](#)). Other brain structures were diffusely involved, including the brainstem, hippocampus, thalamus, basal ganglia, deep white matter, and cerebral cortex, characterized by microglial nodules, scattered clusters of macrophages, and focal necrosis. Severe neuronal loss was present in the inferior olives, and mild pyramidal cell loss was present in the hippocampus. The leptomeninges were involved by a lymphohistiocytic infiltrate. Powassan virus immunohistochemistry revealed numerous infected neurons, including residual Purkinje cells. Powassan virus RNA was detected from formalin-fixed paraffin-embedded brain tissue by RT-PCR and sequencing of the flavivirus *NS5* gene.

Discussion

We present a diagnostically challenging, fatal case of Powassan encephalitis in an immunocompromised patient who was initially seen in December 2016, outside of the typical tick-

Figure 2. Histological Findings From Cerebellar Biopsy and Phylogenetic Tree

borne disease season. The combination of encephalitis and orchiepididymitis is most commonly associated with mumps but has been reported with other neurotropic viruses, including WNV, lymphocytic choriomeningitis virus, and Toscana virus.⁷⁻⁹ It remains unclear whether the testicular symptoms and POWV immunoreactivity represent local viral spread from a tick bite or an early sign of hematogenous spread. A striking feature of this case was the extent of cerebellar involvement, previously identified as a poor prognostic feature.^{3,10} Serum GAD65 positivity raised the possibility of paraneoplastic cerebellitis; however, the antibody is nonspecific, particularly at low titers, and was not detected in the CSF.¹¹ Similar to the 3 previously reported Powassan encephalitis autopsy cases,^{2,4,10} edema, lymphocytic infiltration, gliosis, and microgliosis were diffusely present throughout the brain in our patient. The virus exhibited strong neuronotropism, evidenced by severe loss of neurons in multiple brain regions and by detection of viral antigens in residual neurons.

Conclusions

The optimal method for diagnosis of POWV infection has not been well established because of the rarity of the disease and lack of widely available testing options. Serology is often the preferred method for detection because of the typically narrow window of viremia. In this case, the patient's negative POWV antibody testing and prolonged viremia were likely because of rituximab exposure, and diagnosis depended on detection of virus nucleic acid. Similar seronegative cases^{6,12-14} have been reported for WNV, eastern equine encephalitis virus, and tick-borne encephalitis virus. In the present case, mNGS not only detected viral nucleic acid in CSF but also was able to subclassify the virus as DTV lineage II, a virus with an enzootic cycle distinct from POWV. These results support the utility of unbiased pathogen detection assays capable of detecting a wide variety of infectious agents in cases of encephalitis in which no causative etiology has been identified.
